## Abstract

Deep and shallow embeddings are two popular techniques for embedding a language in a host language with complementary strengths and weaknesses. In a deep embedding, embedded constructs are defined as data in the host: this allows for syntax manipulation and facilitates metatheoretic reasoning, but is challenging to implement—especially in the case of dependently typed embedded languages. In a shallow embedding, by contrast, constructs are encoded using features of the host: this makes them quite straightforward to implement, but limits their use in practice.

In this paper, we attempt to bridge the gap between the two, by presenting a general technique for extending a shallow embedding of a type theory with a deep embedding of its typing derivations. Such embeddings are almost as straightforward to implement as shallow ones, but come with capabilities traditionally associated with deep ones. We demonstrate these increased capabilities in a number of case studies; including a DSL that only holds affine terms, and a dependently typed core language with computational beta reduction that leverages function extensionality.

## 1 Introduction

Hosting a programming language inside another one is one of our favorite pastimes as programming language researchers. Such *embeddings* have proven useful in a variety of domains, ranging from particular applications (such as the design of hardware [9], and the writing of random property-based generators [10]), all the way to the mechanization of the metatheory of such applications (such as Kami [8] or Luck [19] respectively).

The complexity of such embeddings varies significantly depending on the features of both the *object language* and the *host language* involved. For example, embedding a simply-typed object language in a functional host language is a relatively straightforward task, yet one that has proved quite useful in practice, leading to a proliferation of libraries in mainstream ecosystems [26, 25, 17, 22]. On the other hand, embedding a dependently-typed language in another is a highly nontrivial task that gives rise to foundational challenges and that has received significant attention in recent years [1, 18].

Starting with Boulton et al. [5], language embeddings have been broadly classified as either *deep* or *shallow*. An embedding is deep when the terms of the object language are represented as inductive data in the host language. In a deep embedding terms may be arbitrarily manipulated and inspected via the usual mechanism of pattern matching. Deep

■ **Figure 1** A deep embedding of STLC in Agda

embeddings for simply-typed languages are reasonably straightforward to construct, e.g. using an intrinsically-typed representation of terms as an inductive family [3, §3].

By contrast, shallow embeddings directly expand the constructs of the object language in terms of constructs of the host language. In the language of semantics, if a deep embedding can be thought of as defining the *initial* syntactic model of the object language, then a shallow embedding can be thought of as an *arbitrary* semantic model of the object language, but expressed and manipulated in the host language instead of mathematics [5, §5].

## Deep Embeddings

For concreteness, consider the standard (intrinsic) deep embedding for the simply-typed lambda calculus (STLC) in Figure 1. We focus on the fragment consisting of a single base type, and functions. Contexts are lists of types. Variables are positions in that list, viz. de Bruijn indices. Terms are parameterized by a type and context. Every constructor of **Term** represents an STLC typing rule. For example, the **app** constructor takes a term of type  $A \Rightarrow B$  and a term of type  $A$ , and produces produce a term of type  $B$ —parametrically in any context  $\Gamma$ . Functions over the syntax of STLC terms can then be defined using pattern-matching/induction, allowing a plethora of operations (e.g. substitution, reductions, optimizations) and metatheoretic proofs (e.g. admissibility of substitution).

In practice, Agda’s type inference system plays very nicely with intrinsically-typed DSLs. Because the type and context are parameters of **Term**, Agda can infer them in the same way that it would for Agda programs. For example, when given the definition

```
lambda (var same) : Term (base → base)
```

Agda is able to infer that it is well-typed without additional information. It is thus not necessary for the user to specify the type of any part of this expression (e.g. the variable), thereby greatly increasing the usability of the DSL.

However, the same is not true for dependently-typed object languages: because of the presence of the *type conversion* rule

$$\frac{\Gamma \vdash M : A \quad \Gamma \vdash A = B \text{ type}}{\Gamma \vdash M : B}$$

there is considerable overhead in defining a deep embedding of the object language, as we often have to somehow transport terms across type equalities. In practice this overhead is

```

Ctx = Set
Type : Ctx → Set
Type Γ = Γ → Set

∅ : Ctx
∅ = ⊤
cons : (Γ : Ctx) → Type Γ → Ctx
cons Γ T = Σ Γ T

Var : (Γ : Ctx) → Type Γ → Set
Var Γ T = (γ : Γ) → T γ
same : ∀{Γ T} → Var (cons Γ T) (T ∘ proj₁)
same = λ (γ , t) → t
next : ∀{Γ T A} → Var Γ A
      → Var (cons Γ T) (A proj₁)
next x = λ (γ , t) → x γ

Term : (Γ : Ctx) → Type Γ → Set
Term Γ T = (γ : Γ) → T γ

Π : ∀{Γ}
  → (A : Type Γ) → Type (cons Γ A) → Type Γ
Π A B = λ γ → (a : A γ) → B (γ , a)

U : ∀{Γ} → Type Γ
U γ = Set

var : ∀{Γ T} → (icx : Var Γ T) → Term Γ T
var x = x

lambda : ∀{Γ A B} → Term (cons Γ A) B
        → Term Γ (Π A B)
lambda e = λ γ a → e (γ , a)

app : ∀{Γ A B} → Term Γ (Π A B)
      → (a : Term Γ A) → Term Γ (λ γ → B (γ , a γ))
app e₁ e₂ = λ γ → (e₁ γ) (e₂ γ)

```

■ **Figure 2** Shallow embedding of dependent type theory

71 prohibitive, regardless of whether we are using the dependently-typed object language or  
 72 proving things about it.

73 A number of researchers have attempted such deep embeddings of dependently-typed  
 74 languages with varying degrees of success and completeness; see for example [12, 7, 1].  
 75 Each of these attempts represents a complex feat of proof engineering, often using various  
 76 techniques (such as setoids), or assuming certain advanced features in the host language  
 77 (such as quotient inductive types). In contrast to the simply-typed case, a simple, practical  
 78 deep embedding of dependent type theory appears impossible with current technology. This  
 79 invites a search for an easier alternative.

## 80 Shallow Embeddings

81 In contrast, shallow embeddings do not represent terms of the object language as inductive  
 82 data, but rather directly interpret them as values in the host language.

83 For example, consider the shallow embedding of dependent type theory shown in Figure 2.  
 84 Like with the deep embedding, we have definitions of types, contexts, variables, and terms.  
 85 However, unlike the deep embedding, these are not datatypes. Instead, `Ctx` is defined as  
 86 Agda’s universe (called `Set`), and `Type` is the type of families of types over a given context.  
 87 Finally, given a context  $\Gamma$  and type  $T$ , terms and variables are then defined as dependent  
 88 functions  $(\gamma : \Gamma) \rightarrow T \gamma$  over the family  $T$ . Moreover, for each term constructor that we  
 89 had in the deep embedding, we have a corresponding definition in the shallow embedding  
 90 of the corresponding type. For example, the `lambda` definition is defined using an Agda  $\lambda$   
 91 expression, and the `app` definition is defined using standard Agda function application.

92 Thus, each artifact of the object language is interpreted by its counterpart in the host  
 93 language. Owing to its similarity to the set-theoretic model [16, §3] this is sometimes referred  
 94 to as the *standard model* [1, §4], or even the *metacircular interpretation* of type theory [18].

95 This shallow embedding of dependent type theory obviates many of the difficulties one

encounters when trying to define a deep embedding. The reason is that types themselves are no longer mere pieces of syntax, but mathematical objects that are subject to the definitional rules of Agda. Thus, the type equalities we had to transport over vanish [21]. As the shallow embedding inherits the definitional behavior of the host language, we find ourselves in a situation that enables quick and easy prototyping. Unfortunately, there is no free lunch: the fact that our terms are now semantic objects too means that we may no longer pattern-match on them.

### A Middle Ground?

Given the complementary strengths and weaknesses of deep and shallow embeddings, it is natural to ask whether there is something in the middle: is there a form of embedding which is almost as easy to implement as a shallow embedding, but provides some of the extended, syntactic capabilities of a deep embedding?

In this paper we propose an answer to this question, which we call *deeper shallow embeddings*. To build a deeper shallow embedding we need a pre-existing shallow embedding of the object language. Then, the contexts and terms of the deeper shallow embedding are defined by ‘wrapping’ the contexts and terms of the shallow embedding in an inductive data type. Following the technique of McBride [21], the types remain shallowly embedded, so that the host language takes care of type conversion for us.

We claim that deeper shallow embeddings preserve the mathematical simplicity of shallow embeddings, yet add extra capabilities which are useful for writing DSLs. This claim is substantiated by demonstrating these capabilities in practice. For example, we use them to (1) restrict the terms allowed in the DSL, (2) add metadata to terms (and perform computations dependent on this metadata), and (3) do a limited form of pattern-matching (which becomes more powerful in the presence of function extensionality).

Concretely, we make the following contributions:

- We present a way of deepening any shallow embedding, preserving its mathematical simplicity while also gaining additional capabilities that one might expect would require a deep embedding (Section 2). We show it by example on three shallow embeddings: the standard model (Section 2), a standard model for affine terms (Section 3), and a shallow embedding built from an inductive-recursive universe construction (Section 5).
- We demonstrate the usefulness of deeper shallow embeddings through a series of case studies showcasing different features that they exhibit over standard ones: adding metadata, restricting terms, and performing induction over terms (Section 3).
- We consider syntactic transformations such as substitution (Section 4), and show how to further increase the expressive power of a deeper shallow embedding by assuming function extensionality. This gives us the power to define—and compute —  $\beta$ -reduction (Section 5).

All of these results are formalized in Agda. Finally, we discuss related work in Section 6 and conclude by discussing limitations and future directions in Section 7.

## 2 Deeper Shallow Embeddings

As discussed before, a shallow embedding consists of a set of definitions in the host language. The valid object language programs in this embedding are exactly the well-typed terms built by combining these definitions. Thus, given a term  $t$  in the host language (here, Agda), the statement “ $t$  is a term of the shallow embedding” cannot be easily expressed in the host

```

data Context : S.Ctx → Set where
  ∅ : Context S.∅
  _,_ : Context sΓ → (T : S.Type sΓ) → Context (S.cons sΓ T)

data Var : {sΓ : S.Ctx} → (Γ : Context sΓ) → (T : S.Type sΓ) → (S.Term sΓ T) → Set where
  same : Var (Γ , T) (S.weakenT T) S.same
  next : Var {sΓ} Γ A s → Var (Γ , T) (S.weakenT A) (S.next s)

data Term : {sΓ : S.Ctx} → (Γ : Context sΓ) → (T : S.Type sΓ) → S.Term sΓ T → Set where
  lambda : Term (Γ , A) B s → Term Γ (S.Π A B) (S.lambda s)
  var : Var Γ T s → Term Γ T s
  app : Term Γ (S.Π A B) s1 → (x : Term Γ A s2) → Term Γ (λ γ → B (γ , s2 γ)) (S.app s1 s2)
  Π : (A : Term Γ S.U s1) → (B : Term (Γ , s1) S.U s2) → Term Γ S.U (S.Π s1 s2)
  U : Term Γ S.U S.U

```

■ **Figure 3** Deepening the shallow embedding of dependent type theory. Each constructor is a wrapper around a shallow constructor (prefixed by `S`).

language—even if `t` is of a type that is evidently in the image of the shallow embedding. In fact, the ability to do this amounts to solving the *definability* problem in semantics.

By contrast, deeper shallow embeddings *internalize* this statement. By defining an inductive family of contexts and terms, we effectively *tag* the definable elements of the shallow embedding in a way that records their construction. This leaves us with something in between a deep and shallow embedding. On the one hand, our contexts, types, and terms carry elements of a shallow embedding. On the other hand, our typing derivations are deeply embedded in a datatype, so we may pattern-match on them.

To make the idea more concrete, let us revisit the shallow embedding of Figure 2. We will henceforth refer to this shallow embedding as `S`. By definition, to have a term of this shallow embedding means to have a shallow context  $\Gamma : \text{Ctx}$ , a shallow type  $T : \text{Type } \Gamma$ , and a dependent function  $(\gamma : \Gamma) \rightarrow T \gamma$ . To deepen this embedding we must define a new datatype `Term` that is indexed by these three values. The constructors of the datatype encode the typing rules of the theory which it represents. The full definition may be found in Figure 3. All references to definitions in the shallow embedding start with the prefix `S`.

To understand this deepened term type better, we may for instance consider its `lambda` constructor. The  $\lambda$  constructor of the shallow embedding is referred to as `S.lambda`. If `s` is a term of the shallow embedding of the appropriate type and context, then `S.lambda s` represents the  $\lambda$ -abstraction of that term in the shallow embedding. Then, the `lambda` constructor of the deepened embedding inputs a term of a type parameterized by the shallow term `s`, and outputs an expression of type parameterized by the term `S.lambda s`. For clarity we write each deep constructor so that it refers to the corresponding shallow definition, but note that the code repetition could be eliminated by unfolding the definitions of the shallow embedding directly into the constructors of the datatype.

We can of course extend this idea to the construction of contexts and variables as well. The deepened context datatype `Context : S.Ctx → Set` is a family over the contexts `S.Ctx` of the shallow embedding. When we have an inhabitant of `Context sΓ` we know that (1) `sΓ` is a well-formed context in the shallow embedding, and (2) that `sΓ` is definable by starting from the empty context, and extending it by shallow types. Similarly, `Var sΓ sT s` is inhabited when `s` is a well-formed variable in the shallow embedding.

For a quick example of the deepened embedding, here is a definition of the identity

## 23:6 Deeper Shallow Embeddings

171 function on the universe:

```
172   idU : Term ∅ (S.Π S.U S.U) _
173   idU = lambda (var same)
```

174 Notice that Agda is able to infer the corresponding shallow term, which has been elided  
175 and replaced by “\_”. We are always able to extract the shallow term from a deepened  
176 embedding:

```
177   extract : ∀{sΓ Γ T t} → Term {sΓ} Γ T t → S.Term sΓ T
178   extract {sΓ} {Γ} {T} {t} e = t
```

179 Hence, anything that can be proven about shallow embeddings can also be proven about  
180 deeper ones. For example, we can prove consistency (relative to the ambient type theory);  
181 that is, we can show that if we have an inhabitant of the shallow empty type, then we have  
182 an inhabitant of the empty type in the host language:

```
183   consistency : ∀{t} → Term {S.∅} ∅ (λ _ → ⊥) t → ⊥
184   consistency e = (extract e) tt
```

### 185 Syntax and Universe Level Simplifications

186 This entire paper is formalized in Agda (available at <https://www.cs.umd.edu/~llampro/DeeperShallowEmbeddings.zip>). However, to facilitate readability, we have omitted cer-  
187 tain details when presenting Agda code. In particular, we mostly leave out universally  
188 quantified parameters when they can easily be inferred. More importantly, we have also  
189 omitted all traces of universe levels. For example, in the formalization, the **U** constructor of  
190 **Term** looks like:

```
192   U0 : {sΓ Γ} → Term {sΓ} Γ S.U1 S.U0
```

193 Each universe level included in the deeper embedding needs its own constructor, so for  
194 example **U<sub>1</sub>** is a separate constructor. Additionally, **Term** (and its shallow counterpart)  
195 needs some constructors to deal with universe level cumulativity. The full definition has  
196 three additional constructors: **Lift**, which raises a type to the next level; **lift**, which raises a  
197 term to a lifted type; and **lower**, which lowers a term from a lifted type. The corresponding  
198 shallow embedding definitions are implemented with the Agda terms of the same name.

## 199 3 Advantages of Deeper Shallow Embeddings, by Example

200 In this section we show that deeper shallow embeddings have usability advantages vis-a-  
201 vis both shallow and deep embeddings. We do so by example: we present deeper shallow  
202 embeddings which enable features that are not supported otherwise. Our discussion is  
203 focused around three examples: metadata on terms, pattern matching, and term restriction.

### 204 3.1 Metadata: Named Variables

205 Most embeddings of dependently-typed languages in proof assistants such as Agda or Coq  
206 rely on de Bruijn indices for representing and accessing variables: see e.g. [21, 18]. Evidently,  
207 this state of affairs is undesirable from a usability perspective.

We show that a deeper shallow embedding can be used to define a DSL with named variables. This is achieved without changing the standard shallow embedding of dependent types. Instead, the deepened embedding carries *metadata* about terms like a deep embedding could, in particular the names of variables. This way a user of the DSL is able to write `lambda "x" (var "x")` for the identity function, instead of the usual expression `lambda (var same)`. To achieve this, we add a string along with each type in the deepened context:

```
data Context : S.Ctx → Set where
  ∅ : Context S.∅
  _,_::_ : Context sΓ → String → (T : S.Type sΓ) → Context (S.cons sΓ T)
```

This allows us to write a function:

```
findVar : (Γ : Context sΓ) → String →  $\sum_{T, t}$  Var Γ T t
```

which searches for a variable name in the context. If the variable exists, it returns the shallow type and term of the variable as the `Var` value corresponding to it.

Unlike de Bruijn indices, this does not preclude the user from attempting to write a non-sensical term like `lambda "x" (var "y")` in an empty context. To deal with that eventuality we introduce an error type and term

```
data Error : Set where
  error : Error
```

We can now implement functions which, given a variable name, search the context for the corresponding type and term. If the variable is not found, the `Error` type is used.

```
resultType : (Γ : Context sΓ) → String → S.Type sΓ
resultType Γ name with findVar Γ name
... | nothing = λ _ → Error
... | just ((T, t), x) = T

resultTerm : (Γ : Context sΓ)
  → (name : String) → S.Term sΓ (resultType Γ name)
resultTerm Γ name with findVar Γ name
... | nothing = λ _ → error
... | just ((T, t), x) = t
```

We can now implement `Term`. The `var` constructor takes a string as an argument, and uses the aforementioned functions to compute its own type:

```
var : (name : String) → Term Γ (resultType Γ name) (resultTerm Γ name)
```

Finally, we let the `lambda` constructor take a string argument as well:

```
lambda : (name : String) → Term (Γ, name :: A) B s → Term Γ (S.Π A B) (S.lambda s)
```

Putting all of this together, we can now write terms with named variables! For example, the identity function can be written as:

```
id : Term ∅ (λ _ → (X : Set) → X → X) _
id = lambda "X" (lambda "x" (var "x"))
```

So, what if we try to use an unbound variable? Suppose we enter the definition

```

252   id : Term () (λ _ → (X : Set) → X → X) _
253   id = lambda "X" (lambda "x" (var "y"))

```

This definition will not typecheck in Agda! By writing this definition we have communicated to Agda our expected type; we have also fixed the context to be empty. In the process of type-checking, Agda introduces the two variables "X" and "x" in the context, and then looks for "y". It fails to find it, so `var` constructs an element of type `Term Γ (λ _ → Error)` which does not match the stated type, causing a type error.

It is important to note that this technique is possible exactly because (a) `λ _ → Error` is a perfectly acceptable type of the shallow embedding, yet (b) none of our `Term` constructors create elements of `Term Γ (λ _ → Error) (λ _ → error)`.

## 3.2 Pattern Matching and Induction: Compilation

Another drawback of shallow embeddings is that they do not provide the ability to induct on their terms. Given an arbitrary element `t : S.Term nil T`, there is not much we can really do: `T` is an arbitrary family over the empty context, so essentially an arbitrary Agda type. Hence, there is very little we can do, either with the term `t` or the type `T`.

In contrast, terms in the deeper shallow embedding are given by an inductive data type. It is therefore possible to write functions that pattern-match on them. For example, the following function compiles a dependently-typed term to JavaScript.

```

270   compileToJs : Term Γ T s → String
271   compileToJs {Γ} (lambda e) =
272     "function(x" ++ (show (len Γ)) ++ ") " ++ "{" ++ compileToJs e ++ "}"
273   compileToJs {Γ} (var x) =
274     "x" ++ (show ((len Γ) - (index x)))
275   compileToJs (app e1 e2) =
276     "(" ++ (compileToJs e1) ++ " " ++ (compileToJs e2) ++ ")"

```

The compilation proceeds in a fairly obvious way: a `lambda` is compiled to an anonymous function; and variable names are determined by their position in the context, using `len` and `index` to compute the relevant indices. Because of the lack of an induction principle, writing this simple function over a shallow embedding is impossible.

## 3.3 Syntactic Restrictions: Affine Terms

A final advantage of deeper shallow embeddings is that they provide the ability to restrict the terms that appear in the DSL. This has two advantages: (1) on an engineering level, it limits the interface exposed to the DSL programmer to a safer fragment; and (2) on a design level, it enables us to ‘carve out’ a subset of interest of a shallow embedding.

When embedding a DSL in a shallow manner, the intention is that the user will build terms by composing the given definitions. However, shallow embeddings cannot stop a user from writing any term of the base language with a fortuitous type. For example, if one wants an element of `S.Term S. (S.Π S.U S.U)` then instead of writing `S.lambda (S.var S.same)`, one could simply write `λ y x → x`, circumventing the intent of the DSL designer. This example is fairly innocuous, but it is not difficult to imagine that this might become problematic in more complicated languages.

Kaposi, Kovács, and Kraus [18] propose a solution to this that uses Agda records for data hiding. The idea is that we wrap the contraptions of the shallow embedding in unary record

types whose fields are private, and import only the wrapped model. That way the user cannot ‘access’ the underlying representation. However, because of Agda’s  $\eta$ -rule for record types, the wrapped model retains the definitional properties of the shallow embedding.

While this approach works, it relies heavily on features specific to Agda. If we use deeper shallow embeddings instead, only constructors of `Term` can be used to obtain terms. Therefore, the terms of the DSL can be restricted without making use of any data-hiding mechanism.

As an example, we can define a DSL which holds only affine terms, i.e. a DSL whose terms can use a variable in the context *at most once*. First, we need to augment contexts with some usage annotation. We define a family `VarData : Contexts  $\Gamma$   $\rightarrow$  Set` over deepened contexts, which stores a boolean flag for each type in the context. The flag records whether that variable has been used. Next, we inductively define a ternary relation

`Check : VarData  $\Gamma$   $\rightarrow$  VarData  $\Gamma$   $\rightarrow$  VarData  $\Gamma$   $\rightarrow$  Set  $j$`

between flagged contexts, which holds if the first two contexts do not use the same variable, while the third context uses all variables used by either of the first two. This is reminiscent of ternary ‘context split’ relations often used with linear types, e.g. session types [24, §3].

```
data VarData : Context s $\Gamma$   $\rightarrow$  Set where
   $\emptyset$  : VarData  $\emptyset$ 
   $\_ , \_$  : VarData  $\Gamma$   $\rightarrow$  Bool  $\rightarrow$  VarData ( $\Gamma$  , T)

data Check : VarData  $\Gamma$   $\rightarrow$  VarData  $\Gamma$   $\rightarrow$  VarData  $\Gamma$   $\rightarrow$  Set j where
   $\emptyset$  : Check  $\emptyset$   $\emptyset$   $\emptyset$ 
  consLeft : (T : S.Type s $\Gamma$ )  $\rightarrow$  Check  $\Gamma_1$   $\Gamma_2$   $\Gamma_3$   $\rightarrow$  Check ( $\Gamma_1$  , true) ( $\Gamma_2$  , false) ( $\Gamma_3$  , true)
  consRight : (T : S.Type s $\Gamma$ )  $\rightarrow$  Check  $\Gamma_1$   $\Gamma_2$   $\Gamma_3$   $\rightarrow$  Check ( $\Gamma_1$  , false) ( $\Gamma_2$  , true) ( $\Gamma_3$  , true)
  consNeither : (T : S.Type s $\Gamma$ )  $\rightarrow$  Check  $\Gamma_1$   $\Gamma_2$   $\Gamma_3$   $\rightarrow$  Check ( $\Gamma_1$  , false) ( $\Gamma_2$  , false) ( $\Gamma_3$  , false)
```

Next, we define `AffineTerm`, which is a deepened type of terms that only holds affine terms. It is defined in much the same way as the standard deepened term type, but it incorporates elements of `Check` and `VarData` as evidence that the embedded terms are affine. Specifically, this evidence is used in the `app` constructor to ensure that the two subterms do not both use the same variable.

```
data AffineTerm : ( $\Gamma$  : Context s $\Gamma$ )  $\rightarrow$  VarData  $\Gamma$   $\rightarrow$  (T : S.Type s $\Gamma$ )  $\rightarrow$  S.Term s $\Gamma$  T  $\rightarrow$  Set j where
  app : AffineTerm  $\Gamma$   $\Gamma_1$  (S. $\Pi$  A B)  $s_1$   $\rightarrow$  (x : AffineTerm  $\Gamma$   $\Gamma_2$  A  $s_2$ )  $\rightarrow$  Check  $\Gamma_1$   $\Gamma_2$   $\Gamma_3$ 
     $\rightarrow$  AffineTerm  $\Gamma$   $\Gamma_3$  ( $\lambda \gamma \rightarrow B (\gamma , s_2 \gamma)$ ) (S.app  $s_1$   $s_2$ )
   $\Pi$  : AffineTerm  $\Gamma$   $\Gamma_1$  S.U  $s_1$   $\rightarrow$  AffineTerm ( $\Gamma$  ,  $s_1$ ) ( $\Gamma_2$  , b) S.U  $s_2$   $\rightarrow$  Check  $\Gamma_1$   $\Gamma_2$   $\Gamma_3$ 
     $\rightarrow$  AffineTerm  $\Gamma$   $\Gamma_3$  S.U (S. $\Pi$   $s_1$   $s_2$ )
  -- ...
```

Finally, we are at a point where one may clearly witness the power of deeper shallow embeddings and the ability to pattern-match on them. We are able to define a function:

`checkAffine : Term  $\Gamma$  T t  $\rightarrow$  Maybe ( $\Sigma$  (VarData  $\Gamma$ ) ( $\lambda vd \rightarrow$  AffineTerm  $\Gamma$  vd T t))`

which checks whether a given `Term` is affine, and—if so—reconstructs it as an `AffineTerm`. To achieve that we will need some helper functions, whose definitions we omit. Amongst these the most important one is `check`, which inputs two elements of `VarData`, and—if they do not conflict with each other—returns their combination alongside an element of `Check`. The ‘affinization’ function itself recursively calculates the variables used by each expression. Whenever an `app` case is encountered, it checks that no variable is used twice.

## 4 Renamings and Substitutions

Having showcased some advantages of deeper shallow embeddings with small examples, we now turn to the more complicated operations of *renaming* and *substitution* that are central to dependent type theory.

As shallow embeddings are essentially semantic interpretations, substitutions are definable operations. In our running example of the ‘standard’ interpretation, the type of all substitutions is the type of all functions between contexts; the action of a substitution on types and terms is then determined by function application:

```

351 Sub : Ctx → Ctx → Set
352 Sub Γ2 Γ1 = Γ2 → Γ1

353 extend : Sub Γ2 Γ1 → Term Γ1 T → Sub Γ2 (cons Γ1 T)
354 extend sub e γ2 = sub γ2 , e (sub γ2)

357 subType : Sub Γ2 Γ1 → Type Γ1 → Type Γ2
358 subType sub T = λ γ2 → T (sub γ2)

361 lift : (sub : Sub Γ2 Γ1) → (T : Type Γ1) → Sub (cons Γ2 (subType sub T)) (cons Γ1 T)
362 lift sub T (γ , t) = sub γ , t

365 subTerm : (sub : Sub Γ2 Γ1) → Term Γ1 T → Term Γ2 (subType sub T)
366 subTerm sub e = λ γ2 → e (sub γ2)

```

There is no evident non-inductive way to isolate the renamings amongst these.

In contrast, in deep embeddings substitutions are usually given in an algebraic style, and defined inductively from the empty substitution, the identity, composition, weakening, and extension [12, §3.5] [7, §2] [1, §3]. Renamings may also be defined by induction-recursion—at the same time as a recursive function that interprets them as full substitutions [2, §5].

How is one to bridge this gap for deeper shallow embeddings? As before, the answer lies exactly in the middle: we are able to define a data type **Ren** of renamings, which is indexed in shallowly-embedded substitutions. Like with shallow embeddings but unlike with deep embeddings, renamings here have inherent computational content: they are actual functions mapping variables to variables.

```

379 Ren : S.Sub sΓ2 sΓ1 → Context sΓ2 → Context sΓ1 → Set
380 Ren sub Γ2 Γ1 = Var Γ1 T t → Var Γ2 (S.subType sub T) (S.subTerm sub t)

382 lift : Ren sub Γ2 Γ1 → Ren (S.lift sub T) (Γ2 , S.subType sub T) (Γ1 , T)

383 renTerm : Ren sub Γ2 Γ1 → Term Γ1 T t → Term Γ2 (S.subType sub T) (S.subTerm sub t)
384 renTerm ren (lambda e) = lambda (renTerm (lift ren) e)
385 renTerm ren (var x) = var (ren x)
386 renTerm ren (app e1 e2) = app (renTerm ren e1) (renTerm ren e2)
387 renTerm ren (Π A B) = Π (renTerm ren A) (renTerm (lift ren) B)
388 renTerm ren U = U

```

In many ways, our definition resembles the traditional definition of renaming in simply-typed  $\lambda$ -calculus [14, §II.1.1], i.e. a map from variables to variables that respects types. However, making that definition dependent involves quite a bit of tricky indexing [11, §5].

Fortunately, we have no need for that: our deepened renamings are also ‘tracked’ by a corresponding substitution of the shallow embedding, so we can use that instead.

Substitutions work similarly: a deepened substitution `Sub` is parameterized by a shallow substitution, i.e. an element of `S.Sub`. Interestingly, renaming is used to define substitution.

```

402   Sub : S.Sub sΓ2 sΓ1 → Context sΓ2 → Context sΓ1 → Set1
403   Sub sub Γ2 Γ1 = Var Γ1 T t → Term Γ2 (S.subType sub T) (S.subTerm sub t)

406   liftSub : Sub sub Γ2 Γ1 → Sub (S.lift sub) (Γ2 , S.subType sub T) (Γ1 , T)
407   liftSub sub same = var same
408   liftSub sub (next x) = renTerm next (sub x)

409   extend : Sub sub Γ2 Γ1 → Term Γ1 T t → Sub (S.extend sub t) Γ2 (Γ1 , T)
411   extend sub e same = subTerm sub e
412   extend sub e (next x) = sub x

414   subTerm : Sub sub Γ2 Γ1 → Term Γ1 T t → Term Γ2 (S.subType sub T) (S.subTerm sub t)
415   subTerm sub (lambda e) = lambda (subTerm (liftSub sub) e)
416   subTerm sub (var x) = sub x
417   subTerm sub (app e1 e2) = app (subTerm sub e1) (subTerm sub e2)
418   subTerm sub (Π A B) = Π (subTerm sub A) (subTerm (liftSub sub) B)
419   subTerm sub U = U

```

To sum up, with deeper shallow embeddings we can perform complicated *syntactic* operations on embedded terms, such as substitution and renaming. Naturally, one wonders: how far can we take this? For example, could we encode a  $\beta$ -reduction step? We answer that in the next section.

## 5 $\beta$ -reduction and Injectivity of Products

With induction under our belts, it might seem that we have all of the components needed to define one-step  $\beta$ -reduction. After all, we can certainly inductively traverse a term looking for a  $\lambda$ -abstraction to the left of an application, and—if we find one—apply substitution as described in the previous section. Here is a first attempt:

```

430   βreduce : Term Γ T t → Term Γ T t
431   βreduce (lambda e) = lambda (βreduce e)
432   βreduce (var x) = var x
433   βreduce (Π A B) = Π (βreduce A) (βreduce B)
434   βreduce U = U
435   βreduce (app e1 e2) = ?

```

In fact, the completed clauses of this definition are not one-step  $\beta$ -reduction. It will perform more reductions than necessary, as e.g. we recurse on both the left and right subtree of  $\Pi$ . We could rework this definition into a correct one, but this simpler variant suffices to illustrate the point.

Given our syntax, the only computationally non-trivial case is that of `app`. To complete it we would ideally like to check whether the expression is a redex, i.e. whether `e1` is of the appropriate form `lambda e`. If not we can mindlessly recurse like in all other cases; but if we find a  $\lambda$ -abstraction, we would like to perform the substitution. Unfortunately, we are not able to pattern-match on `e1`. The reason is that its type is `Term Γ (S.Π A B) s1`. As `Term`

## 23:12 Deeper Shallow Embeddings

is an inductive family indexed in shallow types, induction is only allowed when we have a term of general type  $\text{Term } \Gamma \text{ } T \text{ } s_1$  with all of  $\Gamma$ ,  $T$  and  $s_1$  free.

Being more precise about the problem we are trying to solve, we would like a function

```
castLam : Term  $\Gamma$  (S. $\Pi$  A B) t  $\rightarrow$  Maybe (Term ( $\Gamma$  , A) B ( $\lambda$  ( $\gamma$  , a)  $\rightarrow$  t  $\gamma$  a))
```

that checks if its argument is a  $\lambda$ -abstraction, and if so returns its body. We can make some progress towards defining such a function by generalizing the  $\Pi$  type to an arbitrary type  $T$ . We may then induct on it; if it happens to be a  $\lambda$ -abstraction, we return a term of type  $\text{Term } (\Gamma , A') \text{ } B' \text{ } t'$  where  $A'$ ,  $B'$ , and  $t'$  have no particular relation to the input.

In fact, we can do better than that. We can define a fairly simple function `castLamImpl` which checks whether its argument is a  $\lambda$ -abstraction. If it is, it returns

- types  $A'$  and  $B'$ , the latter depending on the former,
- the body  $t'$  of the  $\lambda$ -abstraction,
- a proof that  $T \equiv \text{S.}\Pi A' B'$ , and
- a proof that  $t$  is equal to the shallow- $\lambda$ -abstraction of  $t'$ .

All of this is encoded in an ugly nested  $\Sigma$  type, so here we abbreviate the syntax to convey the meaning:

```
castLamImpl : Term  $\Gamma$  T t  $\rightarrow$  Maybe  $\sum_{A,B,t'} \lambda \gamma \rightarrow (T \gamma , t \gamma) \equiv \lambda \gamma \rightarrow$   

  ( $(\text{S.}\Pi A B) \gamma , \lambda a \rightarrow t' (\gamma , a) ) \times \text{Term } (\Gamma , A) B t'$   

  castLamImpl (lambda e) = just ( $\_ , \_ , \_ , \text{refl} , e$ )  

  castLamImpl  $\_$  = nothing
```

One might expect that it would be easy to define `castLam` using the proofs of equality provided by `castLamImpl`. But that is not so! If we apply `castLamImpl` to something of type  $\text{Term } \Gamma \text{ } (\text{S.}\Pi A B) \text{ } t$  we would obtain, amongst other things, types  $A'$  and  $B'$  along with a proof of  $\text{S.}\Pi A B \equiv \text{S.}\Pi A' B'$ . Hence, at the very least, we would have to show that  $p : A \equiv A'$  and  $B \equiv_p B'$ , where the  $\equiv_p$  means that the two types are equal ‘over’ the equality  $p$  of the types on which they depend. In more detail, the exact statement we need is

```
 $\Pi$ -injective :  

  ( $\lambda \gamma \rightarrow ((\text{S}^\top . \Pi A B) \gamma , \lambda a \rightarrow t (\gamma , a)) ) \equiv (\lambda \gamma \rightarrow ((\text{S}^\top . \Pi A' B') \gamma , \lambda a \rightarrow t' (\gamma , a)) )$   

 $\rightarrow (A , B , t) \equiv (A' , B' , t')$ 
```

If we had a proof of this, it would be possible to derive `castLam` from `castLamImpl`:

```
castLam : Term  $\Gamma$  (S. $\Pi$  A B) t  $\rightarrow$  Maybe (Term ( $\Gamma$  , A) B ( $\lambda$  ( $\gamma$  , a)  $\rightarrow$  t  $\gamma$  a))  

castLam e with castLamImpl e  

... | nothing = nothing  

... | just (A , B , t' , p , e') with ( $\Pi$ -injective p)  

... | refl = just e'
```

Using that we could complete the final case of our  $\beta$ -reduction function:

```
 $\beta$ reduce (app e1 e2) with castLam e1  

... | nothing = app ( $\beta$ reduce e1) ( $\beta$ reduce e2)  

... | just e = subTerm (extend idSub e2) e
```

Unfortunately,  $\Pi$ -injective is a very long way from being true. This is a well-known issue in the metatheory of dependent types, known as the *injectivity of type constructors*. To begin, notice that given any Agda types  $A, B, C, D$ , the following statement is not true:

489  $(A \rightarrow B) \equiv (C \rightarrow D) \rightarrow A \equiv C \times B \equiv D$

490 Taking  $A$  and  $C$  to be empty types,  $B$  to be empty, and  $D$  to be the unit type of one  
 491 element, we see that in homotopy type theory [23] the antecedent is true by univalence, yet  
 492 the consequent proves that the empty and the unit types are equal. Thus, neither this, nor  
 493 the corresponding more general statement about dependent function types in Agda, can be  
 494 true. But since  $S.\Pi$  was defined in terms of Agda function types, neither will  $\Pi$ -injective!

495 Additionally, our shallow types are functions from a context to an Agda type. In order  
 496 to prove equality of shallow types, we will therefore also require function extensionality.

## 497 5.1 Type codes: an Inductive-Recursive Universe

498 The problem we faced above boils down to two facts: (1) the types of the shallow embedding  
 499  $S$  were elements of the Agda universe of types  $\text{Set}$ , and (2)  $\text{Set}$  itself is far too *open*. This  
 500 means that we are not in general able to induct on elements of  $\text{Set}$  (i.e. Agda types) so as  
 501 to prove the requisite injectivity lemma. This restriction is only natural: as Agda supports  
 502 new data type definitions, which would change the induction principle of  $\text{Set}$ .

503 The solution is to change the shallow embedding  $S$ , so that its types come from a *closed*  
 504 universe. This can be achieved using a classic construction by Martin-Löf [20], which is  
 505 sometimes known as the *inductive-recursive universe* [13, §1]. The idea is simple: instead  
 506 of having a universe of types, we construct a universe of *type codes*, i.e. an inductive data  
 507 type whose elements represent types. At the same time we define a family over this universe,  
 508 which interprets these codes as types of the host language.

509 The technique itself is best illustrated by example. In fact, as our object language con-  
 510 tains a universe itself, we will generate an infinite hierarchy of universes by simply adjoining  
 511 an additional  $\mathbb{N}$  parameter. This family  $\text{TypeCode} : \mathbb{N} \rightarrow \text{Set}$  of inductive-recursive universes  
 512 is defined as follows. Technically, as written here this definition is not strictly positive.  
 513 However, the full definition in our formalization includes the standard trick of performing  
 514 induction on the  $\mathbb{N}$  parameter so that it is admissible in Agda.

```
515 data TypeCode : ℕ → Set where
516   'U : TypeCode (suc n)
517   'Π : (A : TypeCode n) → ([ A ] → TypeCode n) → TypeCode n
518
519   [ _ ] : TypeCode n → Set
520   [ 'U ] = TypeCode n
521   [ 'Π A B ] = (a : [ A ]) → [ B a ]
```

523  
 525 Notice the distinctive use of induction-recursion in the constructor  $'\Pi$ , which takes a type  
 526 code and a family over the *interpretation* of that type code.

527 We can then build a new shallow embedding whose types are, in fact, type codes. The  
 528 construction amounts to sprinkling the decoding function wherever it should be to turn type  
 529 codes into bona-fide types:

```

Ctxt = Set
Type : ℕ → Ctxt → Set
Type n Γ = Γ → TypeCode n
Term : ∀ {n} → (Γ : Ctxt) → Type n Γ → Set
Term Γ T = (γ : Γ) → [ T γ ]

U : ∀ {n} → Type (suc n) Γ
U = λ _ → 'U

Π : (A : Type (suc n) Γ)
  → Type (suc n) (cons Γ A) → Type (suc n) Γ
Π A B = λ γ → 'Π (A γ) ((λ a → B (γ , a)))
```

The implementation of `Type` is now a function from a context to `TypeCode`, while the implementation of `Term` uses the decoding function. Moreover, notice that types and terms are now indexed by  $\mathbb{N}$ , so they live at various levels of the inductive-recursive universe hierarchy.

Finally, we can deepen this new shallow embedding, not forgetting to thread the new universe levels around in the process. The new definition of `Context`, `Var`, and `Term` looks nearly identical to our original one from Figure 3, except that the prefix `S` now refers to our new shallow embedding with type codes.

## 5.2 Completing the Definition

The benefit of inductive-recursive universes is that, as they are inductively defined, their constructors are injective. As a consequence we are now able to prove the injectivity of `Π`:

```

541   Π-injective-typecode : (('Π A B) , t) ≡ (('Π A' B') , t') → (A , B , t) ≡ (A' , B' , t')
542   Π-injective-typecode refl = refl

```

This is almost a proof of `Π-injective`, with the difference that we must somehow extract proofs `S.Π A B ≡ S.Π A' B'` and `t ≡ t'` from its premise. Looking at the premise more carefully, it roughly gives us what we want, but as an equality of functions:

$$(\lambda \gamma \rightarrow ((S.\Pi A B) \gamma , \lambda a \rightarrow t (\gamma , a))) \equiv (\lambda \gamma \rightarrow ((S.\Pi A' B') \gamma , \lambda a \rightarrow t' (\gamma , a)))$$

By post-composing these two functions with the first projection, we can obtain an equality of the form

$$(\lambda \gamma \rightarrow (S.\Pi A B) \gamma a) \equiv (\lambda \gamma \rightarrow (S.\Pi A' B') \gamma)$$

To turn that into the desired equality, we must also use the *function extensionality* axiom:

```

553   funExt : ((x : A) → f x ≡ g x) → f ≡ g

```

which is not natively available in Agda. However, it is well-known to be consistent with intentional Martin-Löf type theory [23, §2].

To make the behavior of `funExt` somewhat more computational, we add the following *rewrite rule* to Agda:

```

558   postulate
559     funExtElim : funExt (λ x → refl) ≡ refl
561   {-# REWRITE funExtElim #-}
560

```

This definitional equality is known to hold in e.g. the set-theoretic model. With this machinery in place, we are able to complete the definition of  $\beta$ -reduction.

## 6 Related Work

Our approach to deepening shallow embeddings is closely related to McBride’s ‘Outrageous but Meaningful Coincidences’ [21]. In that work, McBride introduces a deeper shallow embedding for dependent type theory by wrapping it in a datatype. The embedding differs from ours in that instead of indexing deepened terms by their shallow counterparts, McBride writes an evaluator that targets the shallow embedding using induction-recursion. While the aesthetics of each approach are debatable, it is a fact that the inductive-recursive interpreter

571 makes it difficult to define syntactic operations like renaming and substitution. This is  
572 because any operations on the terms must include a proof that they commute with the  
573 evaluation function. Our purely inductive definition makes such syntactic transformations  
574 much simpler to define. Our work focuses on the engineering aspects of this technique, and  
575 its various practical uses and advantages over traditional shallow embeddings.

576 Kaposi et al. [18] propose that shallow embeddings are a ‘morally correct’ alternative to  
577 deep embeddings. They consider how one can be sure that a shallow embedding corresponds  
578 to the desired type theory; how does one know that no extra equalities or terms have been  
579 introduced? They prove several such correctness results *externally* to Agda. By contrast,  
580 our deeper shallow embeddings can be seen as bringing some of this work back inside of  
581 Agda. Kaposi et. al. also present a technique for term restriction in shallow embeddings,  
582 which we describe and compare to our techniques in (Section 3.3)

583 Of course, one way to build a maximally-expressive embedding of type theory in type  
584 theory is to actually use a deep embedding. Perhaps the most technically accomplished  
585 work in that direction is by Altenkirch and Kaposi [1], who use *quotient inductive-inductive*  
586 *types* (QIITs) to present a deep embedding of type theory (with explicit substitutions) that  
587 is already quotiented under its own definitional equality. The power of this technique has  
588 been shown by proving normalization results [2].

589 Previous work by Danielsson [12] and Chapman [7] encodes type theory (with explicit  
590 substitutions) in type theory itself. Because it lacks the technology of QIITs, this approach  
591 has to explicitly transport the representations of terms along type equalities using the type  
592 conversion rule.

593 The functional programming community has also explored various forms of embedding.  
594 Gibbons and Wu [15] present a unified approach through polymorphism and folding. Carette  
595 et al. [6] design a system using Haskell typeclasses to build shallow embeddings which si-  
596 multaneously allow users to add new terms at any time but also to define new interpreters.  
597 Another instance of an ‘intermediate’ embedding that is between deep and shallow can be  
598 found in the work of Augustsson [4], where the author hints at the possibility of so-called  
599 *neritic* embeddings.

## 600 7 Conclusion

601 In this paper we presented a technique for *deepening* a shallow embedding by storing it in  
602 a data type. This allows us to inspect, analyze, and manipulate terms in a way that is  
603 usually associated with deep embeddings, while retaining the automation afforded by the  
604 shallow embedding. We demonstrated the practical uses of this technique in a series of small  
605 case studies, and showed how—assuming function extensionality—we can recover syntactic  
606 transformations, such as  $\beta$ -reduction.

607 One application of domain-specific languages is metaprogramming. In Lisp-like lan-  
608 guages, code can be manipulated as data, quoted, and unquoted. Building a typed DSL can  
609 be seen as implementing a typed version of the sort of metaprogramming that Lisp can do.  
610 For example, quoting can be seen as simply writing an element of the DSL, and unquoting  
611 as corresponding to our `extract` functions. One could even imagine that the syntax of the  
612 DSL could look like the syntax of the host language, and therefore the host language would  
613 interpret code as either host code or DSL code depending on the type. Our hope is that  
614 ultimately dependently-typed embedding techniques will yield a typed (and therefore less  
615 error-prone) version of the sort of metaprogramming that one can do in Lisp.

616 Moreover, we explored the idea that there is more than just deep embeddings (initial

models) and shallow embeddings (arbitrary models) in the design space. Unexplored constructions of shallow models harbor additional power, which might be of significant interest for particular applications. In the future, we are hoping to further explore this spectrum of ‘hybrid’ embeddings, with the ultimate goal of a practical approach for encoding a dependent type theory inside a dependent type theory.

Of course, the technique of deepening a shallow embedding has limitations. For example, deeper shallow embeddings allow induction over terms, but not over types. Various steps can be taken to improve that; for example, switching to an inductive-recursive universe allowed us to prove that  $\Pi$  is injective. However, the same trick does not allow us to prove e.g. that  $U$  and  $\Pi$  are unequal.<sup>1</sup>

Finally, it is often the case that we would like to compute syntactic transformations on the terms of an embedded language—like the  $\beta$ -reduction function given in §5—as they might prove useful in compilation, optimizations, etc. Thus, the question of expressivity arises: which syntactic transformations can be expressed over deeper shallow embeddings? We believe that most transformations that can be performed on a shallow embedding can be lifted to its deepened version: as shallow embeddings often ‘quotient away’ numerous differences between terms, any transformation on that level is likely easy to extend to deepened terms, but may require some effort. For example, when we defined renaming and substitution in Section 4, we had to define substitution on the shallow embedding first; when defining  $\beta$ -reduction in Section 5, we had to find a shallow embedding which satisfied certain equalities first, which required some ingenuity. In short, the transformations that can be expressed are not quite as expressive as those over deep embeddings, and may also require additional work.

Because of these restrictions, we view the main benefits of a deeper shallow embedding to be for metaprogramming, rather than for studying the metatheory of type theory.
